ACKNOWLEDGEMENTS

Partial funding for these alfalfa variety trials was provided by the Idaho Agricultural Experiment Station and the University of Idaho Cooperative Extension System. Cooperator growers provided their time, land, and other inputs for management of these trials and appreciation is expressed to them for their support. ***Forage Genetics International*** donated forage quality analyses. The authors wish to thank all who have contributed to the success of this project.

Introduction

This report summarizes the performance of alfalfa varieties tested in extension variety trials conducted in northern Idaho during 2013–2016 crop seasons. The variety trials were located in cooperators' fields at two sites, one each in Lewis and Idaho counties.

Increased field crop yield is the result of a combination of improved agronomic practices and advances in variety development. Trials reported in this publication help producers compare new varieties with widely grown varieties, using field production practices common for their area. The provided information represents crop performance results from specific locations, production practices, and environmental conditions. Relative performance of varieties can change when tested under other environments and production practices. Evaluation of any variety included in these trials should not be construed as recommending any variety over varieties not included in the trials.

Alfalfa Test Procedures

Two alfalfa variety trials were planted in northern Idaho in the spring of 2013. Seeding rates for all entries was a uniform number of seeds planted per square foot (spsf). These rates were determined by weighing 300 seeds of each alfalfa variety. Alfalfa was planted at 15 spsf. All plots were seeded 20 feet long on 5-foot centers using a double-disc opener with 7 rows, 7 inches apart. Seed was planted $\frac{1}{2}$ – $\frac{3}{4}$ inches deep. At each location, each variety was replicated four times in a randomized complete block design. After plants were well established, the beds were cut back to a plot size length of 15 feet with an application of glyphosate using a tractor-mounted, shielded sprayer between plots. Pesticides were applied by the cooperator while treating the remainder of the field surrounding the trial. Fertilizers and pesticides used in the trials are listed in Table 1 for the sites where the information was provided. Planting and swathing operations by University of Idaho personnel were timed to approximately coincide with the cooperator's operations.

Prior to cutting, plot lengths were measured to more accurately determine the harvestable area for each plot. Plots were swathed with a plot-swather using a 5-foot cycle-type cutting bar. Plots were cut at approximately 4-inches of height. Alfalfa from each plot was weighed on site directly after cutting. Subsamples were taken from each plot and dried to determine water-weight in each plot. Plot yields were adjusted to reflect dry weights. In 2013 and 2014, sub-samples were analyzed for forage quality by Northwest Labs, LLC.

Statistical Interpretation

Data in the tables are sorted by yield, with the highest yielding entries listed first. The overall trial average is shown at the bottom of each table. The least significant difference (LSD) and the coefficient of variation (CV) are listed. The LSD is given at the 5 percent error level and aids in comparing varieties. If the measured values of any two varieties within a column differ by the LSD value or greater, they can be considered different with a confidence level of 95%. If the measured values are less than the LSD value, the differences may be due to random error rather than actual varietal differences. If no

significant statistical differences were found among varieties, “ns” (not significant) is shown for the LSD. The CV listed in the tables is given as a general measurement of the precision of each experiment. Lower CV percentage values indicate lower experimental variation and greater precision. A higher CV value indicates abnormal variation within the trial that could be due to external factors such as animal grazing, hail damage, or other variable stress on the plants. CV values were not averaged across trials or years.

Variety choice should take into consideration as much performance data as possible with comparisons across years and locations. In addition to yield, other factors such as protein content, disease resistances, winter hardiness, and any observations from grower experience can be used in deciding on which variety to plant. Due to seasonal variation, caution should be taken when looking at the results from a single growing season.

Growing Conditions and Factors Affecting Trial Results

Both trials were located in silt loam soils at elevations of approximately 3200 ft. On average, the Idaho County trial received less precipitation between October 1 and the date of first cutting (11 inches) when compared with the Lewis County site (16 inches). More favorable precipitation at Lewis County trial is reflected in better yields and higher protein content, on average. 2015 was warmer and drier than average in both locations, but Idaho County suffered more extreme drought conditions which is reflected in starkly lower yields at that location in that year. No significant insect or disease issues were observed at either location.

Trial Locations, Management and Varieties Tested

Table 1. Trial location and management information for Idaho County, ID.

Idaho County Trial						
Year	Rainfall		Fertilizer	Micronutrients	Chemical	
	Oct 1: 1st Cutting*	Date of 1st Cutting	(N-P-K-S fall applied)		lbs/ac	lbs/ac
